<sup>b</sup> Associate Professor, Finance and Accounting Area, Indian Institute of Management Indore, India, 453556

**Abstract:** We investigate whether volatility demand of options impacts magnitude of variance risk premium change. We further investigate whether sign of variance risk premium change conveys information about realized volatility innovations. We calculate volatility demand of options by vega-weighted order imbalance. Further, we classify volatility demand of options into different moneyness categories. Analysis shows that volatility demand of options significantly impacts the variance risk premium change. Among the moneyness categories, we find that volatility demand of most expensive options significantly impacts variance risk premium change. Further, we find positive (negative) sign of variance risk premium change conveys information about positive (negative) innovation in realized volatility.

**Keywords:** Variance risk premium; Volatility demand; Model free implied volatility; Realized variance; Options contract

**JEL Classifications:** G12; G13; G14

# 1. Introduction

It is consistently observed that systematic selling of volatility in options market results in economic gains. Options strategies that engage in selling volatility practice are gaining popularity among practitioners. These strategies prompt practitioners to diversify investment opportunities apart from the traditional asset classes. Theories of finance suggest that economic gains by selling volatility can be attributed to variance risk premium. Variance risk premium is defined as the difference between risk neutral and physical expectation of variance. Expected risk neutral variance consists of information about expected physical variance and market price of the variance risk i.e., variance risk premium. Thus, existence of variance risk premium makes expected risk neutral variance a biased estimator of expected physical variance, and the variance risk is systematically priced. Thus, variance risk premium is an insurance to hedge variance risk.

Many studies investigate the presence of volatility or variance risk premium. For example, Bakshi and Kapadia, 2003; Carr and Wu, 2009; Bollerslev et al. 2009; Garg and Vipul, 2015; document the presence of volatility/variance risk premium. These studies indicate that volatility risk is priced by variance risk premium and document stylized facts about variance risk premium. For example, Bollerslev et al., 2009, 2011; Bekaert and Hoerova, 2014; relate variance risk premium with market wide risk aversion. Carr and Wu, 2009 argue that variance risk is priced as an independent source of risk. But very few studies attempt to understand the determinants of variance risk premium and thus determinants of variance risk premium is very less understood. We take this up and in this study, we strive to understand the magnitude of variance risk premium in a demand and supply framework of options. Previous studies of Bollen and Whaley, 2004; Garleanu et al., 2009, document that net demand of options influences the prices and implied volatility of options. For example, Bollen and Whaley, 2004 show that net buying pressure impacts the implied volatility of options. Similarly, Garleanu et al. (2009) document that market participants are net buyer of index options and demand of options influences prices. Based on these key ideas, we argue that volatility demand of options impacts the variance risk premium. Ni et al. (2008) argue that volatility demand of options contains the information of future realized volatility of the underlying asset. This study uses vega-weighted order imbalance as volatility demand to forecast future volatility. We propose that changes in the expected volatility would change the net demand of volatility in the market place, consequently affecting the implied volatility of options. Thus, magnitude of the

difference between implied variance and realized variance would emerge as a consequence of net volatility demand. Fan et al., (2014) decompose the volatility risk premium into magnitude and direction components. According to them, magnitude and direction of volatility risk premium contain different information. They argue that magnitude of the volatility risk premium reflects the imbalance in demand and supply, while direction or sign of volatility risk premium reflects the expectation of realized volatility. Building on the same, we decompose the change of variance risk premium into magnitude and direction components. We argue that expectation of future realized volatility changes the volatility demand that drives changes in implied volatility. Thus, magnitude of the variance risk premium reflects the divergence or convergence of implied variance change with respect to realized variance change. On the other hand, the sign or the direction of changes of variance risk premium reflects the expectation of realized volatility change. When change in the variance risk premium is positive (negative), trades expect that expected realized volatility would increase (decrease). We investigate empirically how change in the volatility demand affects the magnitude of the variance risk premium, and whether the sign of variance risk premium change reflects the expectation of realized volatility.

Main findings of our study are as follows. First, we find volatility demand of options significantly impacts the variance risk premium change. Second, among moneyness categories, volatility demand of most expensive options significantly impacts variance risk premium change. Third, positive (negative) sign of variance risk premium change conveys information about positive (negative) innovation in realized volatility.

We contribute to the literature in the following way. Studies on the structural determinants of volatility risk premium change are very rare. To the best of our knowledge, this would be among one of the initial studies to investigate the structural determinants of the magnitude variance risk premium change.

The rest of the paper is organized as follows. Section 2 briefly reviews the literature and explains the motivation of the study. Section 3 describes the methodology that provides calculation details of variance risk premium and volatility risk premium. Further it explains the decomposition method of directional and volatility order imbalance components. Section 4 describes the data used for the study and presents the summary. Section 5 reports the results of the empirical tests. Section 6 concludes the paper.

## 2. Background and motivation

We calculate variance risk premium in a model free manner. Model-free implied volatility framework is proposed by Demeterfiet al., 1999; Britten-Jones and Neuberger, 2000. Model-free implied volatility (MFIV) offers a framework to calculate risk neutral expectation of future volatility. Based on the MFIV framework, CBOE introduced volatility index (VIX), which measures the short term expectation of future volatility, in 2003. National Stock Exchange of India (NSE) introduced India VIX in March, 2008 based on the model-free implied volatility framework. We use India VIX as risk neutral volatility expectation. We calculate realized variance in a model free manner by the sum of squared returns. Previous studies of Bollerslev et al., 2009; Drechsler and Yaron, 2011 use five-minutes sum of squared returns to calculate realized variance. We use five-minute sum of squared return to obtain model free realized variance. Although the definition of variance risk premium says ex-ante expectation of realized variance, we subtract ex-post realized variance of thirty calendar days from the current India VIX level (transforming India VIX into its 30 calendar days variance term), and denote it as variance risk premium. This specific way of calculation of variance risk premium makes it observable at time  $t$  and also makes it free from any modelling or forecasting bias. We discuss the details of calculations in methodology section.

The rationale behind variance risk premium can be explained by the mispricing of options. In an ideal world, options are redundant securities. But in practice, there is a strong demand for options because of the numerous reasons. Informed investors may prefer options over the underlying asset because of the high leverage provided by options (Black 1975; Grossman and Sanford 1977). On the other hand, presence of stochastic volatility prompts volatility informed investors to trade on volatility by using non-linear securities such as options (Carr and Wu, 2009). These incentives prompt investors to participate in options trading. Previous studies investigate informational role of options market and discuss whether informed traders trade on options market (Chakravarty et al., 2004). Informed players may use options to trade directional movement information of underlying asset, expected future volatility information of the underlying asset, or any other information by taking long, short positions on call or put options, or different combinations of call and put options. A single underlying asset has wide range of strike prices and multiple maturities. All these make information extraction difficult from options trading. Recently, Holowczak et al. (2014) show how to extract a particular type of information by the aggregate option transactions. For our study, we are interested to extract

information about the volatility demand. We discuss how we follow Holowczak et al. (2014) to extract information about the volatility demand. According to the study of Holowczak et al. (2014), a call option is a positive exposure to the underlying stock price and a put option is a negative exposure to the underlying stock price. Delta of an option measures the sensitivity of the option price to the underlying stock price movement. So assign a positive delta to call options order imbalance and negative delta to put options order imbalance for the same strike price and same maturity. Thus, at aggregate level, order imbalance of call and put options should take opposite signs and the net aggregated order imbalance of call and put combination at that strike and maturity would measure the underlying stock price movement exposure. This method is different than Bollen and Whaley (2004) study where they capture net buying pressure of options. Bollen and Whaley (2004) use absolute delta as a measure of net buying pressure for call and put options. Bollen and Whaley (2004) study argue that net demand of an option contract makes it deviate from its intrinsic values and impacts its implied volatility. Different options contracts for the same underlying experience different net buying pressures. Accordingly, the implied volatilities of these option contracts vary and produce apparent anomaly in the market known as volatility smile or smirk or skew. Coming to the calculation of net volatility demand, Holowczak et al. (2014) argue that vega, which is the sensitivity of the option price to the underlying volatility movement, is same for both call and put options for the same strike price and maturity. That means in an ideal world, traders do not have any reason to prefer one type of options (call or put) over others in trading volatility. Vega is positive for both call and put options. The net volatility demand of a strike and maturity then can be calculated by the aggregated vega-weighted order imbalance of call and put options at that strike and maturity.

One of the stylized facts of implied volatility is, on an average, it exceeds the realized volatilities. Theory suggests that difference is the premium paid by the buyers of the options to the sellers of the options. The buyer of the options pays the premium because of the risk of losses during periods when realized volatility starts exceeding the option implied volatility. Increase in realized volatility coincides with the downside market movement and increase in uncertainty in the investment environment (Bakshi and Kapadia 2003). The extant literature documents the presence of volatility/variance risk premium across different financial markets. Many studies conclude that volatility risk is priced through variance risk premium (Bakshi and Kapadia, 2003; Carr and Wu, 2009; Coval and Shumway, 2001). For example, Bakshi and Kapadia (2003) document the presence of variance risk premium (VRP) by delta hedged option

gains. Using the difference between realized variance and variance swap rate as variance risk premium, Carr and Wu (2009) show strong variance risk premium for S&P and Dow indices. Further, they argue that the variance risk is independent of the traditional sources of risk. In the context of Indian market, Garg and Vipul (2015) document the presence of volatility risk premium. They confirm that option writers make consistent economic profits over the life of the options because of the presence of volatility risk premium.

Previous related studies on options trading and volatility include Bollen and Whaley (2004), and Ni et al. (2008). Bollen and Whaley (2004) explain the shape of implied volatility function (IVF) by the net demand of options. In Black-Scholes framework the supply curve of the options is horizontal regardless of the demand for the options. Bollen and Whaley (2004) argue that supply curve of the options is upward sloping rather than horizontal because of the limits to arbitrage<sup>1</sup>. The upward supply sloping curve of options makes them mispriced from their Black Scholes intrinsic values. Thus net demand of a particular option contract affects the implied volatility of that series and determines the implied volatility function. Bollen and Whaley (2004) measure the net demand of an option contracts by the difference between the numbers of buyer motivated contracts traded and the number of seller motivated contracts traded multiplied by the absolute delta of that option contract. The paper concludes that absolute delta-weighted options order flow impact the implied volatility function. Similarly, Ni et al. (2008) measure volatility demand by the vega-weighted order imbalance. According to Ni et al. (2008), net volatility demand content information about the future realized volatility of the underlying asset. They use volatility demand to forecast future realized volatility.

Our study is related to Fan et al. (2014). This study investigates determinants of volatility risk premium in demand and supply framework. The study argues that supply of options is related to market maker's willingness to absorb inventory and provide liquidity. On the other hand, demand of options emerges from the hedging requirement of tail risk. Investors use put index to hedge tail risk. The study captures demand effect by put option open interest and captures supply effect by credit spread and TED spread. Our study differs from them in many ways. We are interested to understand the change of magnitude of variance risk premium by volatility demand of options. We use vega-weighted order imbalance of options to capture the net demand of options. Moreover, Fan et al (2014) study investigate the level effect of volatility

---

<sup>1</sup> Shleifer and Vishny (1997) proposes limits to arbitrage theory. This theory describes that exploitation of mispriced securities by arbitrageurs is limited by their ability to absorb intermediate losses.

risk premium, where we are interested to capture the magnitude change of variance risk premium in a volatility demand framework. We propose the following testable hypotheses,

H1: Change in net volatility demand influences magnitude change in variance risk premium.

H2: The sign of the change in variance risk premium reflects expectation about the realized volatility innovations.

In the next section, we discuss the detail of the methodology.

### 3. Methodology

This section explains the calculation of variance risk premium. Following that, the section explains calculation details volatility demand from the option order flows. Next we explain empirical the testing methods.

#### 3.1 Volatility risk premium

The formal definition of variance risk premium is the difference between risk neutral and objective expectation of the total return variance i.e.,  $VRP_t = E_t^Q(Var_{t,t+1}) - E_t^P(Var_{t,t+1})$ . Literature employs different proxies for measuring variance risk premium. Moreover, literature uses variance risk premium and volatility risk premium interchangeably. For example, Drechsler and Yaron (2011) measure variance risk premium as  $VRP_t = VIX_t^2 - E(RV)_{t+30}^2$ , where they use CBOE volatility index<sup>2</sup> squared,  $VIX_t^2$ , as the proxy for risk neutral expectation of total return variance and forecast one month realized variance as the proxy for objective expectation of total return variance. Similarly, Bollerslev et al. (2009) use  $VRP_t = VIX_{t,t+1}^2 - RV_{t-1,t}^2$  where  $VIX_{t,t+1}^2$  is a proxy for risk neutral variance measure and  $RV_{t-1,t}^2$  is the proxy for objective variance measure. They use the ex-post realized variance  $RV_{t-1,t}^2$  as objective measure of variance to avoid forecasting bias of realized variance so that variance risk premium is observable at time t. Both the above studies use the sum of five-minute squared return over a month as a proxy for realized variance. Moreover, both the studies treat overnight or weekend

---

<sup>2</sup> "VIX" is the trademarked ticker symbol CBOE volatility index.

returns as one five-minute interval. According to Drechsler and Yaron (2011), this treatment does not bias the realized variance measure. Chen et al. (2016) use  $VRP_t = RV_{t,t+30}^2 - VIX_t^2$ , where they use realized variance as the annualized 30-day (calendar days) return variance. Garg and Vipul (2015) define volatility risk premium as the difference between model-free implied volatility (MIFV) and realized volatility. They use India VIX<sup>3</sup> (IVIX) as the proxy for model-free implied volatility and forecast of two scaled return volatility (TSRV) as the proxy for realized volatility.

We define variance risk premium as,

$$VRP_t = IVIX_t^2 - RV_{t,t+30}^2 \quad (1)$$

where we proxy risk neutral measure by squared India VIX (after transforming into its 30 calendar days risk neutral variance) and realized variance, taking sum of five-minute squared returns over thirty calendar days treating overnight and over-weekend returns as one five-minute interval following Drechsler and Yaron (2011) and Bollerslev et al. (2009). We use ex-post realized variance to avoid forecasting bias. Thus the above measure gives the thirty calendar-day variance risk premium.

### 3.2 Moneyness of options and volatility order imbalance

We define moneyness of an option as  $y = \log(K/F)$ , following Carr and Wu (2009), Wang and Daigler (2011). Here  $K$  is the strike price and  $F$  is the futures price of the Nifty index. As we aggregate vega-weighted order imbalance for each strike and same maturity, for both call and put options, we define following categories of options based on moneyness, for both call and put options.

Table 1: Moneyness categories of options

Category	Label	Range
01	Deep in-the-money call (DITM_CE)	$y \leq -0.30$
	Deep out-of-the-money put (DOTM_PE)	$y \leq -0.30$
02	In-the-money call (ITM_CE)	$-0.30 < y \leq -0.03$
	Out-of-the-money put (OTM_PE)	$-0.30 < y \leq -0.03$
03	At-the-money call(ATM_CE)	$-0.03 < y \leq +0.03$
	At-the-money put (ATM_PE)	$-0.03 < y \leq +0.03$
04	Out-of-the-money call (OTM_CE)	$+0.03 < y \leq +0.30$
	In-the-money put (ITM_PE)	$+0.03 < y \leq +0.30$

<sup>3</sup> India VIX is the volatility index computed by National Stock Exchange of India based on Nifty options order book. For more details refer: [https://www1.nseindia.com/content/indices/white\\_paper\\_IndiaVIX.pdf](https://www1.nseindia.com/content/indices/white_paper_IndiaVIX.pdf)

05	Deep out-of-the-money call (DOTM_CE)	$y > +0.30$
	Deep in-the-money put (DITM_PE)	$y > +0.30$

The categories are defined by moneyness of the options, where moneyness is measured as  $y = \log(K/F)$ , where K= strikeprice of the options and F= Futures price of Nifty index.

We employ tick test to calculate number of traded Nifty options for the period of study. We obtain proprietary Nifty options trades data from National Stock Exchange (NSE) of India. We calculate number of buy and sell traded options using Nifty options trade data. If the trade price is above the last trade price, it is classified as buyer initiated. Similarly, when trade price is below the last trade price, it is classified as seller-initiated. If the last trade price is equal to current trade price, last state of the classification is kept for the current state of trade price. By tick test, we calculate the number of options bought and number of options sold for each moneyness defined above in the period of study. We report the results in Table 1.

We calculate order imbalance of Nifty call and put options for each strike and for same expiry period. We take rolling over period two days prior to expiry of the near month options. We calculate the order imbalance on daily basis by the proprietary snapshot data obtained from NSE. This snapshot data is given for five timestamps in a trading day (we discuss data details in the data section). We create the order book for each timestamp from the snapshot data and we calculate vega-weighted (as well as delta-weighted) order imbalance for each of the timestamp and average the five time stamped vega-weighted (delta-weighted) order imbalance to compute daily vega-weighted (delta-weighted) order imbalance for each strike and same maturity.

Nifty options are European in style and their maturity is identical to those of Nifty Futures. Thus, we use Nifty futures prices following modified Black (1976) model to avoid dividend ratio calculation of Nifty index. The same procedure is followed by Garg and Vipul (2015). We calculate delta of call option as,

$$\Delta_c = N(d_1) \text{ where } d_1 = \frac{\ln(F/K) + \left(r + \frac{\sigma^2}{2}\right)T}{\sigma\sqrt{T}} \quad (2)$$

$$\text{Similarly, put delta is defined as } \Delta_p = N(d_1) - 1. \quad (3)$$

Here F=Nifty futures price, K=Strike price of the options, r=risk free interest rate,  $\sigma$ =volatility of the underlying and T= time to maturity. We obtain risk free interest data from the EPW time series<sup>4</sup> database. We use the daily 91 days Treasury bills YTM in the secondary Government

<sup>4</sup> Refer <http://www.epwfits.in/> for more details about EPW time series database.

Security fixed income market as our proxy for risk free rate of interest. Following Bollen and Whaley (2004), we use the last sixty days realized volatility (based on square root of sum of five minute squared return for the last sixty calendar days) as volatility proxy in Black Scholes equation to calculate  $d_1$ .

The vega of both call and put is defined as,

$$v_{c,p} = F\sqrt{T} N'(d_1) , \text{ where } F=\text{Nifty Futures price, } T=\text{time to maturity.} \quad (4)$$

In equations (2), (3) and (4),  $N(d_1)$  and  $N'(d_1)$  represent the cumulative density and probability density function of the standard normal variable.

We calculate volatility demand by the vega-weighted order imbalance at each strike for the same maturity. It is given by,

$$VOI_{K,T}^{ts} = FN'(d_1)\sqrt{T}[CVI(K,T) + PVI(K,T)] \quad (5)$$

$$\text{where } CVI(K,T) = (BO_t^j - SO_t^j) \cdot \frac{v_c}{\text{Volume}_t} \text{ and } PVI = (BO_t^j - SO_t^j) \cdot \frac{v_p}{\text{Volume}_t}$$

$BO_t^j$  and  $SO_t^j$  represent the number of buy contracts and number of sell contracts outstanding for execution in the order book. We identify buy orders and sell orders that are standing for execution by the buy-sell indicator in the snapshot data. We take first hundred best bid and ask orders, ignoring the rest orders. We scale the difference down by the volume of total buy and sell contracts. Thus, volume represents number of buy and sell orders for the first hundred orders. As we discuss earlier,  $VOI_{K,T}^{ts}$  represents volatility order imbalance at any timestamp  $ts$ , for each day we calculate average of the  $VOI_{K,T}^{ts}$  to get daily order imbalance for each strike.

$VOI_{K,T} = \text{average}(VOI_{K,T}^{ts})$  where  $ts = 11:00:00, 12:00:00, 13:00:00, 14:00:00, 15:00:00$  for each trading day. We divide each of the strike by the moneyness. So accordingly, all the  $VOI_{K,T}$ , that belong to a single moneyness category are aggregated by as follows,

$$AVOI_t^{cat} = \sum_{cat, k=k_1}^{k_n} VOI_{K,T} , \text{ where } cat = 1, 2, 3, 4, 5 \text{ as defined in Table 1.} \quad (6)$$

Here  $k_1$  to  $k_n$  represent the strike prices belonging to the category.

Apart from calculating the vega order imbalance for each moneyness categories, we also calculate the delta order imbalance (directional order imbalance) as a control for our empirical test. Delta order imbalance is given by,

$$DOI_{K,T}^{ts} = N(d_1)COI(K,T) + (N(d_1) - 1)POI(K,T) \quad (7)$$

where  $COI(K,T) = (BO_t^j - ST_t^j) \cdot \frac{\Delta_c}{Volume_t}$  and  $POI(K,T) = (BO_t^j - SO_t^j) \cdot \frac{\Delta_p}{Volume_t}$

We average  $DOI_{K,T}^{ts}$  to calculate daily delta order imbalance or directional order imbalance for a strike on the same maturity,

$$DOI_{K,T} = average(DOI_{K,T}^{ts}) \text{ where } ts = 11:00:00, 12:00:00, 13:00:00, 14:00:00, 15:00:00$$

Then we aggregate the directional imbalance for each moneyness as,

$$ADOI_t^{cat} = \sum_{cat, k=k_1}^{k_n} DOI_{K,T} \text{ , where cat} = 1, 2, 3, 4, 5 \text{ as defined in Table 1.} \quad (8)$$

$k_1$  to  $k_n$  represent the strike prices belonging to the category

For the robustness check we change the order imbalance definition from the number of contracts of best hundred orders to value of the best hundred orders. We define value as number of contracts multiplied by the price (for best hundred orders) for both buy and sell contracts for each strike price.

### 3.3 Empirical testing method

#### 3.3.1 Preliminary regression and magnitude regression equations

We employ the following empirical general equation.

$$\Delta VRP_t = \alpha_0 + \mu Control_t + \sum_{cat} \gamma_t^{cat} AVOI_t^{cat} + \delta_t \Delta VRP_{t-1} + \varepsilon \quad (9)$$

In the above equation, we regress daily change of variance risk premium with the contemporaneous volatility demand over the moneyness categories of options as mentioned in Table 1. In the above equation,  $AVOI_t^{cat}$  denote the volatility demand of options of a particular category.

Now we test the hypothesis 1, where we regress absolute values of daily changes of variance risk premium with contemporaneous volatility demand.

$$|\Delta VRP_t| = \alpha_0 + \mu Control_t + \sum_{cat} \alpha_t^{cat} AVOI_t^{cat} + \beta_t |\Delta VRP_{t-1}| + \varepsilon \quad (10)$$

Equation (10) specification contains the magnitude change of variance risk premium as dependent variable. Equation (10) is employed to understand whether it provides us more insight about the hypothesis 1. Equation (9) and equation (10) consider daily change (absolute change) of variance risk premium.

Further, next empirical test considers daily change of volatility risk premium (instead of daily change of variance risk premium) as the dependent variable. Volatility is nonlinear monotone transforms of variance. For the robustness of results we specify daily change (absolute change) of volatility risk premium as the dependent variable. We define volatility risk premium as,  $VolatilityRP_t = IVIX_t - RV_{t,t+30}$ , where realized volatility is calculated by the square root of sum of five-minute squared returns over thirty calendar days. Below regression equations are specified for the tests.

$$\Delta VolatilityRP_t = \alpha_0 + \mu Control_t + \sum_{cat} \theta_t^{cat} AVOI_t^{cat} + \vartheta_t \Delta VolatilityRP_{t-1} + \varepsilon \quad (11)$$

$$|\Delta VolatilityRP_t| = \alpha_0 + \mu Control_t + \sum_{cat} \mu_t^{cat} AVOI_t^{cat} + \pi_t |\Delta VolatilityRP_t| + \varepsilon \quad (12)$$

The risk neutral volatility is calculated by the India VIX value and appropriately transforming the model free implied volatility into thirty calendar day volatility, since India VIX is disseminated in annualized terms. We estimate all regression equations using the generalized methods of moments (GMM), and report Newey and West (1987) corrected t-statistics with 7 lags. We discuss the set of control variables will choose here.

### 3.3.2 Model building and control variables

First, we choose Nifty returns as one of our control variables. We expect a negative relationship between magnitude of variance risk premium change and Nifty returns. This is because negative returns of Nifty increases implied volatility. Previous studies (Giot 2005; Whaley 2009; Badshah 2013; Chakrabarti 2015) document that a negative and asymmetric relationship exists between return and implied volatility. Extant literature documents that high volatility is a representative of high risk (Hibbert et al. 2008; Badshah 2013) and high volatility coincides with negative market returns (Bakshi and Kapadia, 2003). So, in times of negative market movement, variance risk premium should go up.

Next control variable is Nifty traded volume. We include traded volume because traded volume and volatility both together influence by information flow. We expect a positive relationship

between Nifty volume and magnitude of variance risk premium. This is because increase of traded volume of Nifty implies lower volatility (Bessembinder and Seguin, 1992), and lower volatility in turn lowers the magnitude of variance risk premium. We apply natural logarithm to scale down the Nifty volume.

Our next set of control variable consists of  $ADOI_t^{cat}$  i.e., delta order imbalance. We control for delta order imbalance following Bollen and Whaley (2004). Bollen and Whaley (2004) show that absolute delta weighted order imbalances impact implied volatility. The way we calculate the delta-weighted order imbalance is different from the Bollen and Whaley (2004). Our delta-weighted order imbalance contains information about the directional movement of Nifty, so we expect delta-weighted order imbalance should not impact magnitude of variance risk premium change.

Our explanatory variable consists of volatility demand  $AVOI_t^{cat}$  for different categories of options. We are ignoring category 01 and category 05 options due to their thin traded volumes. Our category 02 consists of in-the-money call (ITM\_CE) and out-of-the-money put (OTM\_PE) options. Relationship between volatility demand at category 02 options and absolute change in variance risk premium would depend on whether net demand of in-the-money call (ITM\_CE) or out-of-the-money put (OTM\_PE) has got dominating impact on magnitude change of variance risk premium. Similarly, category 03 options consists of at-the-money call (ATM\_CE) and at-the-money put (ATM\_PE) options. We expect a positive relationship between the demand of ATM\_CE and ATM\_PE options and change in absolute variance risk premium. This is because, at-the-money options are most sensitive to volatility changes. So, increase in demand of ATM options would have positive impact on implied volatility, in turn on magnitude of variance risk premium change. Category 04 options consists of in-the-money put (ITM\_PE) and out-of-the-money (OTM\_CE). Relationship between volatility demand at category 04 options and absolute change in variance risk premium would depend on whether net demand of in-the-money put (ITM\_PE) or out-of-the-money call (OTM\_CE) has got dominating impact on magnitude change of variance risk premium. Later on, to understand the effect of volatility demand on individual category of call and put options, we run separate regression with magnitude change of variance risk premium as dependent variable. We keep lagged term of dependent variables as a control variable in the regression equations.

### 3.3.3 Empirical test with sign of change of variance risk premium

We discuss earlier that magnitude and sign of the change of variance risk premium have got different information. Here we test whether sign of the change of variance risk premium contains information about the expectation of realized volatility innovations. Fan et al. (2014) discuss that when volatility risk premium is positive (negative), market participants believe that future realized volatility would be higher (lower). This is the expectation hypothesis given by Ait-Sahalia et al. (2013). On a similar line of argument, we test whether sign of variance risk premium change conveys any information regarding the realized volatility innovations. Based on that we test hypothesis 2 as,

$$\Delta RV_t = \alpha_0 + \alpha_1 \text{sign}(\Delta VRP_t) + \varepsilon \quad (13)$$

We expect  $\alpha_1$  to be positive, because when there is a positive (negative) change in variance risk premium, market expectation is realized volatility change would be higher (lower). Equation (13) is estimated by generalized methods of moments (GMM), and report Newey and West (1987) corrected t-statistics with 30 lags due to overlapping data. Next section describes data and sample of the study.

## 4. Data and Sample description

This section gives an overview about the Indian equity market. Then we explain data sources. Lastly we present the summary statistics of variables.

### 4.1 Indian derivatives market

Indian equity markets operate on nationwide market access, anonymous electronic trading and a predominantly retail market; all these make the Indian stock market the top most among emerging markets. National Stock Exchange of India (NSE) has the largest share of domestic market activity in the financial year 2015-16, with approximately 83% of the traded volumes on equity spot market and almost 100% of the traded volume on equity derivatives. The NSE maintained global leader position in the category of stock index options, by number of contracts

traded, in 2014-15 as per the Futures Industry Association Annual Survey. Also, as per the WFE Market Highlights 2015, the NSE figured among the top five stock exchanges globally in different categories of ranking in the derivatives market.

Nifty is used as a benchmark of Indian stock market by NSE, which is a free float market capitalization weighted index. It consists of 50 large cap stocks across 23 sectors of the Indian economy. We use Nifty as market index in our study. The volatility index, India VIX, was introduced by NSE on March 3, 2008, and it indicates the investor's perception of the market's volatility in the near term (thirty calendar days). India VIX is computed using the best bid and ask quotes of the out-of-the-money (OTM) call options, and OTM put options, based on the near and next month Nifty options order book.

## *4.2 Data Sources*

Sample period of the study ranges from 1<sup>st</sup> July, 2015 to 31<sup>st</sup> December, 2015. We obtain proprietary Nifty options trade data from NSE. NSE trade data provides the details of trade number, symbol, instrument type, expiry date, option type, corporate action level, strike price, trade time, traded price, and traded quantity for each trading day. We use NSE trade data to calculate number of buy trades and number of sell trades happened over the study period i.e., 01<sup>st</sup> July, 2015 to 31<sup>st</sup> Dec, 2015 by the tick test as mentioned in the methodology section. We obtain snapshot data consists of order number, symbol, Instrument type, Expiry date, Strike price, Option type, Corporate action level, quantity, Price, Time stamp, Buy/Sell indicator, Day flags, Quantity flags, Price flags, Book type, Minimum fill quantity, Quantity disclosed, Date for GTD. We use regular book as book type section. These are the order book snapshots at 11 am, 12 noon, 1 pm, 2 pm and 3 pm in a trading day. We obtain minute data of Nifty from Thomson Reuters DataStream. We use minute data to calculate five-minute squared return to find realized variance of the Nifty index. We obtain daily Nifty adjusted closing prices, Nifty traded volume and Nifty Futures prices from NSE database. We obtain risk free interest data from the EPW time series database, as mentioned in the methodology section.

## *4.3 Statistics of variables*

### *4.3.1 Trading activity of Nifty options*

Table 2 reports the number of Nifty options traded for the period of 01<sup>st</sup> July, 2015 to 31<sup>st</sup> December, 2015.

Table 2: Summary of the number of Nifty options traded for the period of 1<sup>st</sup> July, 2015 to 31<sup>st</sup> December, 2015.

This table summarizes the total number of call purchase, total number of put purchase across categories classified by moneyness of the options. It also presents the net purchase of call and put options across categories. Categories are defined in Table 1.

Category	Buy Call	Sell Call	Buy Put	Sell Put	Call Contracts		Put Contracts		Call	Put
					No. of contracts	Proportion of contracts	No. of contracts	Proportion of contracts	Net purchase of contracts	Net purchase of contracts
<b>Category 01</b> (DITM_CE and DOTM_PE)	337550	334400	19500	23475	671950	0.000039	42975	0.000002	3150	-3975
<b>Category 02</b> (ITM_CE and OTM_PE)	46436025	46523975	1499116125	1543271775	92960000	0.005394	3042387900	0.176538	-87950	-44155650
<b>Category 03</b> (ATM_CE and ATM_PE)	2919770975	3001981825	2544880225	2630805125	5921752800	0.343617	5175685350	0.300325	-82210850	-85924900
<b>Category 04</b> (OTM_CE and ITM_PE)	1417336475	1457551150	61255950	63846525	2874887625	0.166819	125102475	0.007259	-40214675	-2590575
<b>Category 05</b> (DOTM_CE and DITM_PE)	18000	22725	44100	36425	40725	0.000002	80525	0.000005	-4725	7675
<b>Total</b>	<b>4383899025</b>	<b>4506414075</b>	<b>4105315900</b>	<b>4237983325</b>	<b>8890313100</b>	<b>0.5159</b>	<b>8343299225</b>	<b>0.4841</b>	<b>-122515050</b>	<b>-132667425</b>

Trading activity of the Nifty options reveals some important aspects. First, total trading activity on call options (51.59%) is greater than on put options (48.41%). Unlike the developed markets, where trading activity in put index options are greater than call index options (specially S&P 500 index options), the Indian market has greater trading activity on call options than on put options. Second, moneyness wise, trading activity on ATM call and ATM put are largest compared to other moneyness categories. Moreover, proportion of trading activity on ATM call options (34.36%) is substantially greater than ATM put options (30.03%). OTM put and OTM call are the next largest traded options (OTM call contributes 16.68% and OTM put contributes 17.65%). ITM call and ITM put come next as contributors to the trading activity. However, percentage wise their contribution is much less (ITM call 0.53% and ITM put 0.72%). Third, interestingly, the net purchase shows that the market is net seller of options across all categories except DITM put and DITM call. But the proportion of DITM put and DITM call are negligible. For that matter, trading activity proportion in category01 and category05 are negligible. Therefore we ignore category01 and category05 for all empirical tests.

#### 4.3.2 Variance risk premium

We calculate variance risk premium (VRP) by Equation (1) i.e.  $VRP_t = IVIX_t^2 - RV_{t,t+30}^2$ . We take risk neutral variance by squared India VIX (transforming into its one month variance terms), which is calculated by the model free implied volatility (MFIV) framework, as proxy. We calculate ex-post realized variance by the sum of five-minute squared returns over thirty calendar days. NSE disseminates India VIX in terms of annualized volatility. We square India VIX and divide it by 12 to transform it into monthly variance. Below is the summary statistics of  $VRP_t$ ,  $\Delta VRP_t$ ,  $|\Delta VRP_t|$ ,  $MFIV_t$  and  $RV_t$ , along with Nifty returns ( $RNifty_t$ ).

Table 3: Panel A is the descriptive statistics of monthly variance risk premium ( $VRP_t$ ), daily change of variance risk premium ( $\Delta VRP_t$ ), daily magnitude change of variance risk premium ( $|\Delta VRP_t|$ ), realized variance ( $RV_t$ ) (monthly), Model free implied variance ( $MFIV_t$ ) (monthly), and daily return of Nifty ( $RNifty_t$ ) for the period 01Jul2015 to 31Dec2015.

Panel C: Autocorrelation functions

Lag	$VRP_t$	$\Delta VRP_t$	$ \Delta VRP_t $	$MFIV_t$	$RV_t$	$RNifty_t$
1	0.944**	0.297**	0.477**	0.923**	0.975**	0.343**
2	0.857**	-0.156	0.235**	0.806**	0.941**	0.019
3	0.786**	-0.126	0.056	0.739**	0.902**	-0.055
4	0.727**	-0.052	0.013	0.710**	0.859**	-0.105
5	0.674**	0.093	0.124	0.688**	0.809**	-0.087

Above we report in parentheses the t-statistics on the significance of mean of  $VRP$ ,  $MFIV$ ,  $RV$  and  $RNifty_t$ , adjusted for serial dependence by Newey-West method with 30 lags. \*, \*\*, \*\*\* denote the statistical significance at 1%, 5%, and 10% level respectively.

Panel A shows that the mean of the variance risk premium is significantly greater than zero, so are  $MFIV_t$  and  $RV_t$ . Thus, variance risk premium exists in Indian options and this result is consistent with Garg and Vipul (2015). Further, mean of magnitude change of variance risk premium ( $|\Delta VRP_t|$ ) is significantly greater than zero, which is not the case for change of variance risk premium ( $\Delta VRP_t$ ). The standard deviation of  $|\Delta VRP_t|$  is less than  $\Delta VRP_t$ . This shows magnitude of variance risk premium change is less volatile than signed variance risk premium change.  $VRP_t$ ,  $\Delta VRP_t$ ,  $|\Delta VRP_t|$ ,  $RNifty_t$  series are significant after removing trend and intercept component from them. These show that these series are trend and intercept

stationary. Panel B shows the correlations among the variables.  $VRP_t$  and  $RV_t$  have strong negative correlations. On the other hand,  $VRP_t$  and  $MFIV_t$  have strong positive correlations. But  $MFIV_t$  and  $RV_t$  do not show significant statistical correlations. Autocorrelation functions of  $VRP_t$ ,  $MFIV_t$  and  $RV_t$  show that these series are strongly correlated and all the reported five lags are significant. We observe the  $VRP_t$  maintains autocorrelations up to thirty lags though we do not report the autocorrelation coefficients of  $VRP_t$ ,  $MFIV_t$  and  $RV_t$  series here for brevity.  $\Delta VRP_t$  does not show autocorrelation more than one lag. Similarly,  $|\Delta VRP_t|$  does not show autocorrelation more than two lags.

Figure 1 shows the realized variance and model free implied variance (MFIV) plot for the period 1<sup>st</sup> July, 2015 to 31<sup>st</sup> December, 2015. It is observed that MFIV is consistently higher up to mid-July, and after the month of August i.e., from the starting of September, 2015.

Figure 1: Realized variance and MFIV plot (01Jul2015 to 31Dec2015)

One reason of MFIV being less than RV, especially during the month of August 2015, may be because of distress in the market due to the China slowdown that affected the Indian market significantly. We plot the VRP (variance risk premium) dynamics for the period 1<sup>st</sup> July, 2015 to 31<sup>st</sup> December, 2015 in Figure 2. We observe that VRP is less than zero during mid-July to August, 2015. This may be due to the reason stated above. Previous studies Bollerslev et al.,

2009, 2011; Bekaert and Hoerova, 2014; relate the variance risk premium with the market wide risk aversion. Economic intuition is straight forward in case of positive variance risk premium. But what is puzzling is the economic intuition of negative variance risk premium. Fan et al.(2014) argue that the sign of negative volatility risk premium can be related to the delta-hedged gains or losses of volatility short portfolios.

Figure 2: VRP dynamics plot (01Jul2015 to 31Dec2015)

We plot change of variance risk premium and magnitude change of variance risk premium in Figure 3 and Figure 4.

Figure 3: Change of variance risk premium (01Jul2015 to 31Dec2015)

Figure 4: Change of absolute variance risk premium (01Jul2015 to 31Dec2015)

#### 4.3.3 Statistics of the variables

Table 4, Panel A represents the correlations among main variables. Here  $ADOI_t^{02}$ ,  $ADOI_t^{03}$ ,  $ADOI_t^{04}$  represent aggregate delta order imbalance and  $AVOI_t^{02}$ ,  $AVOI_t^{03}$ ,  $AVOI_t^{04}$  represent aggregate vega order imbalance (volatility demand) for category category02 (ITM call and OTM put), category03( ATM call and ATM put), category04 ( OTM call and ITM put) respectively. We observe that both  $\Delta VRP_t$  and  $|\Delta VRP_t|$  maintain significant negative correlations with Nifty return ( $RNifty_t$ ).  $AVOI_t^{04}$  has negative correlation with  $RNifty_t$ . Further,  $AVOI_t^{04}$  has negative correlation with  $|\Delta VRP_t|$ . Similarly,  $AVOI_t^{03}$  maintains positive correlation with  $RNifty_t$  and  $|\Delta VRP_t|$ . Although these correlations are not statistically significant. Further analysis on correlations for individual call and put option categories are shown in Panel D. Here we segregate the aggregated demand of each category (02, 03, and 04) into volatility demand components for call and put options. Category 02 consists of ITM\_CE and OTM\_PE. Here  $VDOTM\_CE_t$ ,  $VDATM\_CE_t$ ,  $VDITM\_CE_t$  represent volatility demand for OTM call, ATM call, and ITM call options and  $VDOTM\_PE_t$ ,  $VDATM\_PE_t$ ,  $VDITM\_PE_t$  represent volatility demand for OTM put, ATM put, and ITM put options respectively. We observe that volatility demand of ITM put ( $VDITM\_PE_t$ ) maintains negative correlations with

Table 4: Correlations, Autocorrelation function and summary statistics of the variables. ( We report in parentheses the t-statistics on the significance of mean adjusted for serial dependence by Newey-West method with 7 lags . \*, \*\*, \*\*\* denote the statistical significance at 1%, 5%, and 10% level respectively)

$\Delta VRP_t$ ,  $|\Delta VRP_t|$ , and  $RNifty_t$ . Further, the negative correlation is statistically significant for  $|\Delta VRP_t|$ . On the other hand,  $VDOTM\_CE_t$  shows positive correlation with  $|\Delta VRP_t|$ , and it is not statistically significant and lower in terms of absolute value. So, we assume that increase in volatility demand of  $VDITM\_PE_t$  decreases absolute change of variance risk premium, in turn category 04 options negatively impacts  $|\Delta VRP_t|$ . Both  $VDATM\_CE_t$  and  $VDATM\_PE_t$  maintain positive correlation with  $|\Delta VRP_t|$ , therefore we assume ATM options (category 03) impacts  $|\Delta VRP_t|$  positively. That is increase in volatility demand of ATM options increases  $|\Delta VRP_t|$ . Category 02 options ( $VDOTM\_PE_t, VDITM\_CE_t$ ) show opposite correlations with  $|\Delta VRP_t|$  and none of them is statistically significant.

Panel B shows autocorrelation function of the main variables. We observe  $\log(Vol_{Nifty})_t$  has significant autocorrelations up to seven lags, though we do not report the coefficients up to ten lags due to brevity. Therefore, we choose Newey-West t-statistics with 7 lags.

Panel C and Panel E shows summary statistics of the variables. Mean of all the aggregated volatility demand components  $AVOI_t^{02}, AVOI_t^{03}, AVOI_t^{04}$  are significantly positive. In case of individual options, mean of all the put option's volatility demand are significantly positive, whereas mean of volatility demand at OTM and ATM call options are significantly positive. All these variables (aggregated and individual volatility demand) are stationary.<sup>5</sup> Next we discuss the pattern of the implied volatility skew for the period of study.

#### 4.3.4 Implied volatility skew

We compute the Black Scholes implied volatility skew of the options for the period 1<sup>st</sup> July, 2015 to 31<sup>st</sup> December, 2015. We observe that volatility skew of Nifty options form forward skew.

Figure 5: Implied volatility skew of Nifty options

---

<sup>5</sup> Note that trading volume is not stationary. We do not detrend volume following Lo and Wang (2000). They fail to detrend the volume without adequately removing serial correlation. Therefore, the paper advises to take shorter interval when analyzing trading volume (typically 5 years). Our study period interval is only 6 months.

The volatility skew pattern shows that OTM call options and ITM put options are expensive. Further, we observe that ITM put options are even more expensive than OTM call options.

## 5. Empirical results

In the empirical test section, we start with equation (9), where we regress change of variance risk premium with the set of independent variables and control variables as mentioned in the equation specification.

### 5.1 Empirical results (change of variance risk premium)

Table 5 reports the result of the equation (9). Results show that aggregate delta order imbalances ( $ADOI_t^{02}, ADOI_t^{03}, ADOI_t^{04}$ ) do not have any statistical significance on the changes of variance risk premium for model (2) and (3). Further, aggregate volatility demands ( $AVOI_t^{02}, AVOI_t^{03}, AVOI_t^{04}$ ) do not show any statistical significance in model (4) except in model (2), where  $AVOI_t^{02}$  impacts change of variance risk premium negatively.  $Adj R^2$  of the models show that model (1) best explains the relationship, followed by model (4). For all the

models, coefficients of aggregate delta order imbalance and aggregate vega order imbalance maintain consistency in their signs. We observe that coefficient of  $ADOI_t^{04}$  have negative signs

Table 5: Table shows the results of Equation (9)  $\Delta VRP_t = \alpha_0 + \mu Control_t + \sum_{cat} \gamma_t^{cat} AVOI_t^{cat} + \delta_t \Delta VRP_{t-1} + \varepsilon$ . Models (1), (2), (3), and (4) are the GMM estimates of the variables shown in the table. t-statistics are computed according to Newey and West (1987) with 7 lags. \*, \*\*, \*\*\* denote the statistical significance at 1%, 5%, and 10% levels respectively.

Variable	(1)	(2)	(3)	(4)
<i>Intercept</i>	-0.00719* (-1.96)	-0.0063* (-1.84)	-0.00718* (-1.90)	-0.00644* (-1.91)
<i>RNifty<sub>t</sub></i>	-0.00031*** (-2.91)	-0.00033*** (-2.66)	-0.00032*** (-2.88)	-0.00031** (-2.61)
$\log(Vol_{Nifty})_t$	0.00037* (1.95)	0.00032* (1.82)	0.000377* (1.89)	0.00033* (1.90)
$ADOI_t^{02}$		0.00093 (1.49)	0.00043 (0.85)	
$ADOI_t^{03}$		-0.00135 (-1.66)	-0.00133 (-1.38)

$AVOI_t^{03} (\times 10^{-6})$		1.347 (0.96)		1.166 (0.99)
$AVOI_t^{04} (\times 10^{-6})$		-0.489 (-0.30)		-0.580 (-0.36)
$\Delta VRP_{t-1}$	0.2026** (2.30)	0.2228** (2.62)	0.2179** (2.59)	0.1941** (2.16)
<i>Adj R<sup>2</sup></i>	0.3549	0.3465	0.3451	0.3506
#Obs	120	120	120	120

For all the models. Similarly, coefficients of  $ADOI_t^{03}$  have positive signs and coefficients of  $ADOI_t^{02}$  have negative signs. Coefficients of  $\Delta VRP_{t-1}$  has positive signs for all the models. Continuing with our hypothesis 1, we test whether equation (10) with magnitude of absolute change of variance risk premium as dependent variable can provide us better insights about the relationship. The results of equation (1) can be found in Table 6.

## 5.2 Empirical results (magnitude of variance risk premium change)

Table 6 shows the result of equation (10). The magnitude regression improves *Adj R<sup>2</sup>* for all the models. In the magnitude regression, model (4) best explains the relationship among all other models.

Table 6: Table shows the results of Equation (10)  $|\Delta VRP_t| = \alpha_0 + \mu Control_t + \sum_{cat} \alpha_t^{cat} AVOI_t^{cat} + \beta_t |\Delta VRP_{t-1}| + \varepsilon$ . Models (1), (2), (3), and (4) are the GMM estimates of the variables shown in the table. t-statistics are computed according to Newey and West (1987) with 7 lags. \*, \*\*, \*\*\* denote the statistical significance at 1%, 5%, and 10% levels respectively.

Variable	(1)	(2)	(3)	(4)
<i>Intercept</i>	-0.00766** (-2.11)	-0.00751** (-2.11)	-0.00787** (-2.11)	-0.00729** (-2.09)
<i>RNifty<sub>t</sub></i>	-0.00021** (-2.27)	-0.00024** (-2.32)	-0.00022** (-2.15)	-0.00022** (-2.41)
$\log(Vol_{Nifty})_t$	0.00041** (2.15)	0.00040** (2.15)	0.00042** (2.15)	0.00039** (2.13)
$ADOI_t^{02}$		0.00027 (0.78)	0.00016 (0.46)	
$ADOI_t^{03}$		-0.00079 (-0.81)	-0.0010 (-0.96)	
$ADOI_t^{04}$		0.00021 (0.68)	0.00018 (0.57)	
$AVOI_t^{02} (\times 10^{-6})$		0.142 (0.32)		0.261 (0.50)
$AVOI_t^{03} (\times 10^{-6})$		1.184* (1.76)		1.131* (1.85)
$AVOI_t^{04} (\times 10^{-6})$		-1.93 (-1.53)		-1.99 (-1.54)
$ \Delta VRP_{t-1} $	0.3710*** (2.83)	0.3599*** (2.95)	0.3749*** (2.83)	0.3598***
<i>Adj R<sup>2</sup></i>	0.4241	0.4290	0.4154	0.4391
#Obs	120	120	120	120

We observe that *Intercept*, *RNifty<sub>t</sub>*, and  $\log(Vol_{Nifty})_t$  do not change their signs with absolute value change of variance risk premium. In the equation (10),  $ADOI_t^{04}$  and  $AVOI_t^{02}$  reverse their signs. Everything else maintain consistency in terms of their signs. For model (2) and model (4) volatility demand of ATM options remain statistically significant. Further, volatility demand of ATM options positively impacts the magnitude change of variance risk premium. The reason could be, ATM options are most sensitive to the volatility change. Therefore, market participants with volatility information would prefer to trade in ATM options. Moreover, in Table 1, we see that ATM options are the most traded options in the list of all the categories. For all the categories of options, it is seen that delta order imbalances do not have any impact on change of variance risk premium, which is as per our expectation.

Coefficients of nifty returns (*RNifty<sub>t</sub>*) both equation (9) and (10), for all the models are consistently negative. That is as per our expectation and consistent with the previous studies of Giot 2005; Whaley 2009; Badshah 2013; Chakrabarti 2015, that state negative returns increases

the implied volatility and high volatility is a representative of high risk (Hibbert et al. 2008; Badshah 2013). Increase in implied volatility in turn increases variance risk premium, thus, Nifty returns have negative impact on change as well as on magnitude change of variance risk premium.

Coefficients of logarithm volume is positive both for equation (9) and (10) for all the models as per expectation. This is because higher trading volume implies lower volatility (Bessembinder and Seguin, 1992) and lower volatility in turn lowers the magnitude of variance risk premium.

Table 6 shows that volatility demand of ATM options have significant positive impact on magnitude of variance risk premium change. We further regress magnitude of variance risk premium change with the volatility demand of individual call and put options.

### *5.3 Empirical results (magnitude of variance risk premium change with volatility demand of call and put options)*

We report the results of the regression in Table 7. Results show that  $Adj R^2$  of the model increases with volatility demand components of call and put options. Further, we see volatility demand at ATM and ITM put options are statistically significant. Volatility demand of call options are insignificant. Volatility demand of ATM put options have positive impact on magnitude of variance risk premium change, whereas, ITM put options have negative impact on magnitude of variance risk premium change. The sign of the impact is evident from the correlation analysis in Table 4, where we have seen volatility demand at ITM put options maintain negative correlation with magnitude of variance risk premium change and ATM put options have positive correlation with magnitude of variance risk premium change. Another support for the evidence is the volatility skew pattern for the period of study. We see that ATM and ITM put options are expensive relative to other put options. So volatility trading activity at ATM and ITM put options may have impact on the magnitude of variance risk premium.

Table 7: Table shows the results of equation  $|\Delta VRP_t| = \alpha_0 + \mu Control_t + \sum_{call,put} \alpha_t^{call,put} VDI + \beta_t |\Delta VRP_{t-1}| + \varepsilon$ . Model (1) is the GMM estimates of the variables shown in the table. t-statistics are computed according to Newey and West (1987) with 7 lags. \*, \*\*, \*\*\* denote the statistical significance at 1%, 5%, and 10% levels respectively.

Variable	(1)
<i>Intercept</i>	-0.00762 ** (-2.22)
<i>RNifty<sub>t</sub></i>	-0.00024 ** (-2.41)
$\log(Vol_{Nifty})_t$	0.00041 ** (2.15)
$VDOTM\_CE_t (\times 10^{-6})$	-0.869 (-0.85)
$VDATM\_CE_t (\times 10^{-6})$	0.834 (0.94)
$VDITM\_CE_t (\times 10^{-6})$	0.791 (0.75)
$VDOTM\_PE_t (\times 10^{-6})$	0.274 (0.79)
$VDATM\_PE_t (\times 10^{-6})$	1.81* (1.81)
$VDITM\_PE_t (\times 10^{-6})$	-6.74*** (-2.92)
$ \Delta VRP_{t-1} $	0.3034*** (2.66)
<i>Adj R<sup>2</sup></i>	0.4489
<i>#Obs</i>	120

From the analysis of Table 5 and Table 6 results it is evident that equation (10) better describes the relationship between magnitude of variance risk premium and volatility demand of options. It is apparent that the sign of the variance risk premium change introduces additional noise, which makes the explanation difficult. With the magnitude of variance risk premium change as dependent variable, the statistical clarity of the data increases.

#### 5.4 Empirical results (robustness checks)

We conduct robustness tests of our models. We have done first robustness test by taking order imbalance in terms of value (quantity\*price) in magnitude regression. Table 9 reports the results. We see that estimates are consistent, with no meaningful change in the result other than magnitude of the estimated coefficients.

Volatility is non-linear monotone transformation of variance. Thus, we also estimate the coefficients with change (absolute change) of volatility risk premium. Results are reported in Table 10, Table 11 and Table 12. We observe that results are mostly consistent when we estimate coefficients taking change of volatility risk premium. No meaningful change is observed. When we estimate coefficients with the magnitude of the volatility risk premium change, results are consistent with the results of magnitude of variance risk premium change throughout, other than magnitude of the estimated coefficients. Table 9, Table 10, Table 11, and Table 12 can be found in Appendix section.

These empirical tests confirm hypothesis 1 i.e., change in net volatility demand influences the change in variance risk premium.

### 5.5 Empirical results (Sign test)

We test hypothesis 2 by equation (13). The results can be found in Table 8. According to our hypothesis, sign of variance risk premium change should indicate expectation about the change of realized volatility. We expect a positive coefficient of  $sign(\Delta VRP_t)$ , because if hypothesis holds true then, a positive (negative) sign should indicate increase (decrease) in realized volatility. Results of equation (8) shows that coefficient of  $sign(\Delta VRP_t)$  is positive and statistically significant at 10% level. This result confirms our hypothesis 2, although the  $Adj R^2$  is very less.

Table 8: Table shows the results of equation  $\Delta RV_t = \alpha_0 + \alpha_1 sign(\Delta VRP_t) + \varepsilon$ . Model (1) is the GMM estimates of the variables shown in the table. t-statistics are computed according to Newey and West (1987) with 30 lags. \*, \*\*, \*\*\* denote the statistical significance at 1%, 5%, and 10% levels respectively.

Variable	(1)
<i>Intercept</i>	0.000052 * (1.74)
$\Delta RV_t$	0.000029 * (1.82)
$Adj R^2$	0.0161
#Obs	120

Fan et al. (2014) discuss that sign of volatility risk premium contains the information of delta-hedged gains or losses of option portfolios. Further analysis in this regard can be taken up in the future course of this study.

## **6. Conclusion**

In this paper, we investigate whether volatility demand of options impacts the magnitude of variance risk premium change. We further investigate whether sign of variance risk premium change conveys information about realized volatility innovations. We calculate aggregated volatility demand by vega-weighted order imbalance. Further, we classify aggregated volatility demand of options into different moneyness categories.

Analysis shows that aggregated volatility demand of options significantly impacts the magnitude of variance risk premium change. We explore the nature of impact for different moneyness categories. Results show that aggregated volatility demand at ATM options positively impacts variance risk premium. Further we analyse the impact of volatility demand of call and put options on magnitude of variance risk premium change. We find, volatility demand of ATM and ITM put options significantly impact the variance risk premium change. Volatility skew pattern (for the period of study) supports this finding, as ATM and ITM put options remain expensive for the period of study. We conduct several robustness tests of our results. These test results show that findings of the study are also consistent with volatility risk premium.

We find sign of variance risk premium change conveys information about realized volatility innovations. Positive (negative) sign of variance risk premium change indicates positive (negative) realized volatility innovation.

Thus, the study concludes that volatility demand information in options order flow impacts the volatility/variance risk premium while nature and degree of the impact depend on the market structure.

Table 11: Table shows the results of Equation (12)  $|\Delta VolatilityRP_t| = \alpha_0 + \mu Control_t + \sum_{cat} \mu_t^{cat} AVOI_t^{cat} + \pi_t |\Delta VolatilityRP_t| + \varepsilon$ . Models (1), (2), (3), and (4) are the GMM estimates of the variables shown in the table. t-statistics are computed according to Newey and West (1987) with 7 lags. \*, \*\*, \*\*\* denote the statistical significance at 1%, 5%, and 10% levels respectively. We calculate order imbalance by value (price\*quantity).

Variable	(1)	(2)	(3)	(4)
<i>Intercept</i>	-0.058* (-1.72)	-0.05507* (-1.82)	-0.05834 (-1.76)	-0.05363* (-1.73)
